

ON THE DYNAMICS OF SOCIAL TIES STRUCTURES IN GROUPS

Joep Sonnemans^a, Frans van Dijk^b and Frans van Winden^a

Abstract

Economic behavior often takes place in small groups of people interacting with each other (like work teams and boards of directors, but also social networks and neighborhoods). Characteristic of such interaction is the development of (affective) interpersonal relationships, or social ties. The embeddedness of economic behavior in networks of social ties seems to have a profound impact on the outcome of economic processes. In this paper we investigate experimentally the development of social ties structures through economic interaction in a public good environment. It turns out that complicated dynamics arise from individual differences in social value orientation and affective response patterns.

*This paper is part of the EU-TMR Research Network ENDEAR (FMRX-CT98-0238). At the time of the experiment Frans van Dijk was affiliated with CREED. Financial support from the Netherlands' Organization for Scientific Research (NWO) is gratefully acknowledged. We are thankful to Siegwart Lindenberg for his comments on an earlier version of this paper. We also thank Otto Perdeck for the development of the software used in the experiment. An earlier version of this paper was titled: "Group formation in a public good experiment". We thank two referees of this journal for very helpful comments.

1. Introduction

Economic behavior, in the private as well as the public sector, often takes place in groups of small numbers of people interacting with each other. Think of work teams, committees, boards of directors, governmental bureaus, but also households and neighborhoods. At closer inspection, this even happens in situations modeled by standard economic theory as involving the anonymous interaction of many agents. Examples are competitive commodity markets and corporate shareholding. In many commodity markets small networks of entrepreneurs, subcontractors and customers exist (Granovetter 1985, Uzzi 1996, 1999). And, in case of public companies, shares are often heavily concentrated in the hands of a small number of major shareholders (La Porta *et al.* 1998).¹ In all these settings people often have little or no choice with whom to interact, since the cost of leaving the group may be very high. While in the theoretical many-agents abstraction the dynamics of social relationships may be safely neglected, this is not so in the real world of small number interaction. In small groups affective influences like personal chemistry, emotions, antagonisms or affinities become relevant. The following statement by Boonstra, at that time CEO of Philips Electronics, illustrates: “A company is a concentration of human emotions (...) Sometimes you want to achieve something, and you observe that it will not happen. Then, waves of emotions play a role, and bridges cannot be built. Most conflicts in organizations occur because emotions are not controlled”.² Sociologists have forcefully argued that the embeddedness of economic behavior in networks of affective interpersonal relationships (social ties) has a profound impact on the economic performance of markets and organizations (see, e.g., Coleman 1984, Turner 1999).³

For these reasons, we think it is appropriate and productive to pay more attention to social dynamics in an economic context. This paper is intended to contribute to the development of this line of research. Specifically, our goal is to investigate experimentally the development of (affective) social ties structures in groups through economic interaction in a public good environment. By focusing on the emergence and dynamics of social ties, instead of the consequences of the assumed existence thereof, this paper addresses in our view an

¹ According to La Porta *et al.*(1998), worldwide the average ownership of the three largest shareholders in publicly traded companies is 46 percent. They conclude that dispersed ownership of public companies is a myth.

² Interview in the Dutch newspaper Volkskrant, 24-12-1998 (translated from Dutch).

³ In economics, the importance of social ties for economic behavior was already noticed by Adam Smith (1759 [1759], part IV, section II): “Colleagues in office, partners in trade, call one another brothers; and frequently feel towards one another as if they really were so. Their good agreement is an advantage to all.” In a similar vein Alfred Marshall (1961 [1890]) related labor market rigidity to the reluctance of workers to migrate due to old associations.

important lacuna in the existing literature. The use of laboratory experimentation as research method is helpful in this respect, since a solid empirical study of the dynamics of interpersonal relations is difficult to achieve in the field, due to observational and control problems. Our focus on how groups develop in a public good environment, moreover, seems relevant for various (political) economic contexts. One major context is the functioning of organizations. Key characteristic of many work situations is synergy of the efforts of groups of workers and unobservability of individual effort. As a result, work processes can be represented in an abstract way by the private provision of public goods. Organizational studies have well established that the social structure of an organization clearly affects the willingness of its members to cooperate, coordinate, share information, and to trust and support one another, which obviously influences its performance (e.g., Scott 1981, Forsyth 1990). Other situations where social networks play an important role concern the wide class of goods and services that have a public good character and are not amenable for provision through markets. One can think of a variety of phenomena, ranging from local crime prevention and environmental protection to voter turnout (political participation).

To make clearer how social interaction affects economic outcomes we need to be more specific about the notion of a social tie. Following a survey on interpersonal attachments (Baumeister and Leary 1995), we consider the affective component - sentiments - the key element of a tie. Sentiments that individuals have with respect to specific others are closely related to the extent they care about the well-being of those others, which suggests a formalization in terms of utility interdependence (Coleman 1984). However, it is important to note that a social tie is not simply determined by the weight that an individual attaches to the well-being or utility of another subject.⁴ This would only be the case if individuals are neutral towards people they do not know. If positive or negative sentiments are maintained towards others in general, a social tie with a specific individual can only be said to exist if the weight attached to this specific other's well-being differs from the weight given to the well-being of others in general (a generalized other).⁵ Therefore, to establish the existence of a social tie, two interpersonal orientations need to be measured: the orientation of an individual towards

⁴ In the sociological literature a social tie is usually seen as a mutual, two-sided relationship. A tie between individuals i and j would then consist of i 's sentiments about j and j 's sentiments about i . However, for ease of exposition and because sentiments are often not symmetric (see Wellman 1988), we will speak of i 's social tie with j without immediate reference to j 's sentiments about i , and vice versa.

⁵ Of interest in this respect are the results of public good experiments. Among experimentalists there is a growing consensus that different types of individuals exist (see Ledyard 1995). There are some who (almost) never contribute to the public good, when it is a dominant strategy for rational selfish individuals not to do so, whereas others (almost) always contribute. This may well be related to differences in attitudes towards others in general.

the interests of an unknown, generalized other, and the orientation towards the interests of a specific individual. In the experiment this will be done with the help of the 'circle -test' as a measuring device (see section 2). The next question is how social ties - providing an intrinsic motivation to advance (if positive) or harm (if negative) the interests of the specific others involved - develop. It is generally acknowledged that ties develop through prolonged interaction, and erode when the interaction ends (Feld 1981, Granovetter 1985, Coleman 1990, Levine and Moreland 1998). Dependent on whether the interaction is valued positively or negatively, positive or negative sentiments are formed (Homans 1950, Feld 1981, Fararo 1989). It may be expected therefore that (rudimentary) social ties will develop during a repeated public good game, as studied in this paper, and that these ties will depend on the payoff of the interaction.

Our research is based upon the theoretical work of van Dijk and van Winden (1997) and is related to the experiments reported in van Dijk, Sonnemans and van Winden (2002). In these experiments, first, the value orientation of the subjects was measured. Then, pairs of subjects played a multi-period public good game. And, finally, the attitudes of the subjects towards their partners were measured. We found that social ties were developed during the public good game, and the value of the ties depended on the success of the interaction. While two-person interaction provides a necessary test of the theory, further tests are necessary for at least two reasons. First, it is hard to tell whether these results also hold in more realistic, larger group settings. Second, it is conceivable that subjects are in a good (bad) mood after an (un)successful interaction and the attitude measured after the interaction is a general effect of this mood, and not specific for the partner. In a four-person group situation we can measure the attitudes towards the different group members, which enables us to investigate whether subjects discriminate between group members and have a more positive (negative) tie with members who contributed more (less). Furthermore, considering groups instead of dyads allows for more complicated social tie structures (e.g. group members having positive ties to some fellow members but negative ties to others).

The organization of this paper is as follows. Section 2 goes into the design and procedures of the experiment. Results are presented in section 3, while section 4 concludes.

2. Design and procedures of the experiment

In four sessions a total number of 56 students participated. On average 25 Euro were earned by the subjects in about 1.5 hours. The experiment was completely computerized.

Each session started with an application of the 'circle -test' (see below), followed by 32 periods of a repeated four-person public good game. The payoff structure of the public good game was explained with a table on the computer screen and on a handout, and subjects had to calculate some outcomes to check understanding. The table was also projected on the wall to show subjects that everybody had the same table. The number of periods (32) was also public knowledge. Subjects did not know, however, that the public good experiment would be interrupted after period 25 for a second application of the circle -test. We decided to apply the second circle test before the publicly known end of the public good game, because we are interested in the social ties in a continuing relationship and in this way we can also study the relationship between the social tie and the behavior in the last periods (note that in van Dijk, Sonnemans and van Winden 2002 the results were qualitatively the same when the second ring test was applied before or after the last period).

In the second application of the circle test, subjects had to perform the test three times, where the Other in these tests concerned the subjects A, B and C, respectively (their fellow group members in the public good experiment). The results of all 25 periods of the public good experiment remained accessible to them on the lower part of the screen. Subjects could scroll to see their own decisions as well as the decisions of the A, B and C subject.

The public good experiment was restarted after everybody had finished the three circle-tests, and periods 26-32 were played. After the experiment, subjects filled in a short questionnaire and were subsequently paid, one at a time, in another room.

The results of the circle tests were only revealed at the very end of the experiment, just before the payment, to avoid that the circle test could be used strategically to influence the behavior of the other subjects⁶. Details concerning the circle-tests and the public good game are discussed next. A translation of the instructions is provided in the Appendix.

⁶This is very different from recent studies (Fehr and Gächter 2002, Masclet et al. 2003, Sefton et al. 2002, Ostrom et al. 1992) that focus on the effect of sanctions and rewards on cooperation. In these studies no pre-test is used and therefore no social ties are measured.

Circle-test

To measure social ties we will use an instrument inspired by the so-called ‘ring-test of social value orientation’ (Liebrand 1984). The ring-test asks subjects to make a series of 24 choices between own-other payoff combinations. Each own-other payoff combination allocates a positive or negative amount of money to the decision maker her/himself and to the subject with whom the individual is anonymously matched. The pairs of allocations lie on a circle with the origin as center (which explains the name of the test). The horizontal axis measures the amount of money allocated to the person her- or himself (S), and the vertical axis the amount of money allocated to the other (O). Each allocation can be considered as a vector. If for each subject the preferred allocations are added, the angle of the resulting vector with the horizontal axis is a measure of the extent the individual cares about the other. The ring-test has proven to be a useful tool for measuring attitudes towards an unknown, *generalized* other (called social value orientation by psychologists). The predictive validity of the test has been shown by many studies (see, e.g., Rusbult and van Lange 1996). For an application in an economic experiment see Offerman, Sonnemans and Schram (1996).

For measuring attitudes towards several specific others the ringtest in its original form is not practical. Repeated measurements would result in too many questions and would cost too much time. We therefore developed the circle -test. In the circle -test the attitude of a subject towards someone else is measured by only one decision⁷. Subjects are requested to select a point on a circle that is presented to them on the computer screen, where each point on the circle represents an allocation of money to the person her/himself (S) and another person (O). The amounts allocated can be positive or negative, with $S^2 + O^2 = (1000)^2$, and are expressed in points (where 200 points are equal to 1 Dutch guilder, approximately 0.45 euro or 0.5 US dollar). Figure 1 shows the computer screen of the circle-test. Subjects receive computerized instructions. They have to practice using the mouse or keyboard to select an allocation of money, and they have to answer some questions correctly before proceeding (to check understanding). The circle-test starts with the computer program displaying a circle without an arrow. When the subject clicks somewhere on the circle, an arrow is displayed and in the right upper part of the screen the amounts for Self and Other are shown. The subject can move the arrow by clicking on the circle or using the keyboard. Every time the amounts in the right upper part of the screen are updated. The final decision has to be confirmed.

⁷ In previous experiments where the ring test was used, a small group of subjects had to be excluded from the analyses because of the low consistency of their choices. The drawback of measuring the attitude by only one decision is that we cannot observe the consistency. This may add noise to the data.

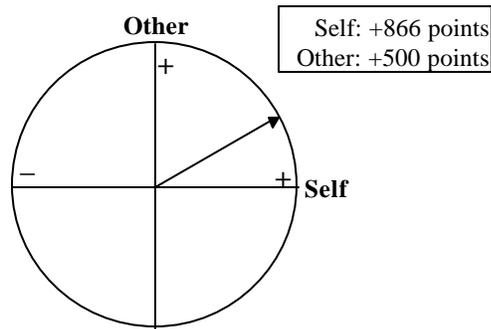

Figure 1 The computer screen of the circle-test. The position of the arrow can be changed by clicking with the mouse on the circle or using the keyboard. The numbers (points) shown are automatically updated. In the three circle-tests after the 25 periods of the public good game, a scrollable table with results of the public good game is displayed in the lower part of the screen.

The experiment starts with a circle-test to measure the attitude towards an anonymous (generalized) Other. The public good game played subsequently is (unexpectedly) interrupted after the 25th period and three more circle -tests are carried out. In each of these tests the Other is one of the group members in the public good game, labeled A, B or C. During the tests the subjects can still see the results of the public good game: the decisions of the A, B and C member, and their own decisions in the game. In this way, the circle -tests can measure whether the attitude of a subject towards a group member is influenced by the behavior of this group member in the public good game. For example, one would expect a more positive (less negative) angle towards a member who contributed more in the game.

Public good experiment

Many interactions in groups have characteristics of a public good game. For example, in a work team individuals decide how much effort they put into the team task and in neighborhoods residents can help to make the neighborhood nice, clean and safe. Therefore we designed the group interaction as a public good game.

Subjects were randomly assigned to a four-person group. The composition of the groups stayed constant for all 32 periods. The other three group members were identified as A, B and C. In each period a subject had to distribute an endowment of 10 markers over two activities *X* and *Y*. Activity *X* generated earnings exclusively for the subject her/himself (private account), whereas activity *Y* generated earnings for all group members (public account). For each subject

the endowment of markers was the same in all periods. Every marker in the public account earned 7 points for all group members, while the value of i markers in the private account was: $21 * i - i^2$. Fixed costs of 60 points were subtracted each period.

The first period started after everybody had finished the computerized instructions. Each period subjects had to type in how many markers they wanted to spend on activities X and Y . After each period they received feedback about the number of markers spent by each other group member (A, B, and C) on activity Y and their own earnings. In the lower part of the screen the decisions and results of previous periods were displayed. Subjects could access information about all previous periods by using the page-up and page-down keys.

Under the usual (benchmark) assumption of rational own-payoff maximization, the subgame-perfect Nash equilibrium of the game has each player put 3 markers in the public account and 7 markers in the private account. The Pareto-optimal outcome, on the other hand, entails that subjects put all markers into the public account. Players earn 122 points in the Nash equilibrium and 220 points in the Pareto-optimal outcome, where 100 points are equal to 50 Dutch Guilder cents, or 45 euro cents.

3. Results

In this section we first present some general results concerning the measurement of sentiments (the post-test) social ties (the difference between post tests and the pre test) and the public good experiment. This is followed by a discussion of the formation and impact of social ties. Finally, we go into the typology of the observed social ties and network of social ties within groups.

3.1 Measurement of social ties and contributions to the public good

Measurement of social ties

The outcomes of the first ('pre') circle-test and the three second ('post') circle-tests can be summarized as follows. The mean of the angles in the post-tests (11.2°) differs hardly from the mean angle in the pre-test (13.4°). A small negative drift of -2° is observed. This disguises, however, the changes that took place at the individual level. The mean of the absolute differences between the pre- and post-tests is 13° . This goes together with an increase of the

standard deviations (from 15.7 to 19.3). Of the 55 subjects⁸, 14 chose an angle of approximately 0° ($-5^\circ \leq \text{angle} \leq 5^\circ$) in both the pre- and the post-tests, while 13 chose approximately 0° in the pre-test and a positive or negative angle in at least one of the post-tests. Only 3 subjects chose 0° in the post-tests only. Thus, the number of subjects that consistently or only later on displayed purely selfish behavior is relatively small. Not surprisingly, 98% of the angles fell within the interval $[-45^\circ, 45^\circ]$, which implies that the absolute weight attached to the Other's payoff is almost never larger than 1. The increase in the standard deviation of the pre- and post-tests angles could be caused by subjects differentiating between their group members. It may also be caused by groups going through different experiences. We will see that both factors play a role.

Table 1. Positive, neutral and negative attitudes of subjects towards others.

	<i>positive</i>	<i>neutral</i>	<i>negative</i>	<i>total</i>
social value orientation (pre-test)	26 (47%)	28 (51%)	1 (2%)	55
sentiments towards specific subjects (post-tests)	80 (48%)	73 (44%)	12 (8%)	165
social ties (difference of post- and pre-tests)	41 (25%)	76 (46%)	48 (29%)	165

Note: neutral attitudes are defined as attitudes between -5° and $+5^\circ$.

Results can also be expressed in percentages of positive, neutral or negatives attitudes. Table 1 illustrates. Negative social value orientations (pre-test angles) hardly occur but negative sentiments towards specific subjects (post-tests angles) occur more often. Negative social ties (the angle post-test is smaller than the pre-test angle) occur as much as positive ties. In 46% of the cases no ties were formed. Of the subjects with a neutral pre-test, about half score neutral in all three post-tests, and the other half developed at least some social ties.

To check the validity of the social ties measurement, we included in the debriefing questionnaire the sociometric question whether they would want to continue with their current partners (asked for A, B and C, separately) or preferred to be matched with another subject, in case the public good experiment were repeated. One would expect that the more positive the tie with a person the stronger the inclination to continue with this person. The results are supportive. The correlation coefficients concerning the willingness to continue, on the one hand,

⁸ Of the 56 subjects, one person did not understand the instructions of the test. The subject expressed this confusion in the debriefing questionnaire. This led to erratic choices, as the subject changed her or his interpretation of the test during the post-tests. The data for this person are not analyzed.

and sentiments and social ties, on the other hand, are .46 and .36, respectively. Both are significant at the .001 level.

Public good game

Figure 2 shows the mean contributions to the public good by period. On average, subjects contribute persistently and substantially more than the Nash equilibrium for own-payoff maximizers would imply, except for the last period. Towards the end the (for this type of game usual) decline occurs (see, e.g., Ledyard 1995). The interruption after period 25 shows no effect on contributions: the contributions in period 25 do not differ significantly from those in period 26 (two-tailed Wilcoxon test, at the group level: $p=.7598$)⁹.

Between groups large differences exist. In the next subsection we will investigate to what extent social value orientations and social ties can shed a light on the observed development of contributions.

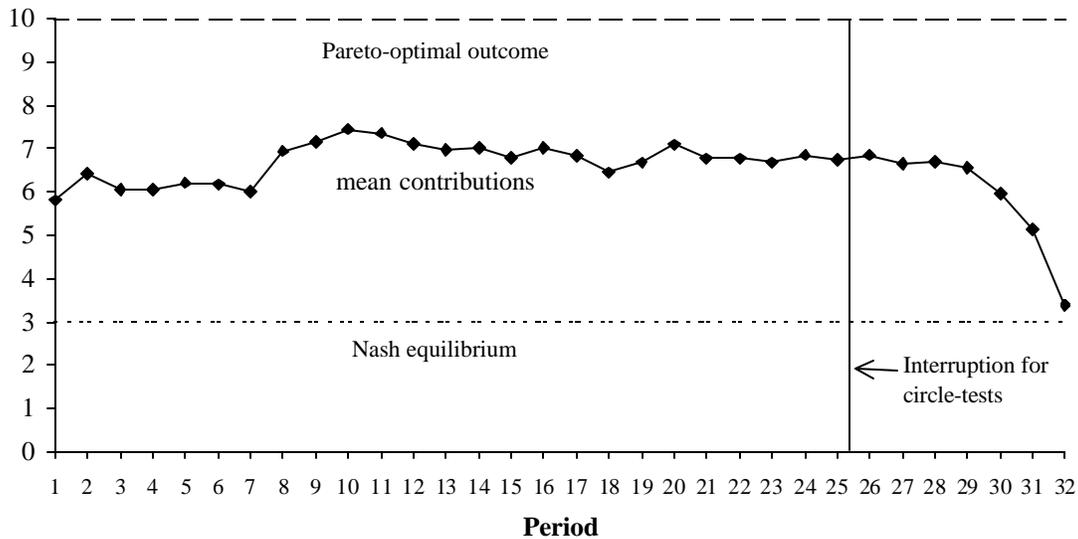

Figure 2. Average individual contributions to the public good per period.

⁹A common problem in attitude, preference and opinion measurement is that the researcher is not sure whether the measured preference was already there or is formed as a result of the measurement. If our subjects would only start thinking about how they felt towards their fellow group members as a result of the second circle test, this would probably change their behavior in the round 26. We interpret the similarity between rounds 25 and 26 as an indication that the existence of social ties is not an artifact of the experimental situation.

3.2 Formation and impact of social ties

Formation of social ties

Our hypothesis is that social ties arise as a result of the interaction in the public good game. First, we address the question whether subjects who contributed more to the public good are more appreciated by their group members than subjects who contributed less. For each subject we calculate the average sentiment of the three partners towards this subject (the average angle of the post-tests). This sentiment correlates positively with the contributions of the subject in periods 1-25 of the public good game (Pearson correlation $R=0.51$). The average social tie towards a subject also correlates positively with the contributions of that subject ($R=0.49$). All these correlations are statistically highly significant ($p<0.01$).

Of course, one would expect that the attitude of a subject towards a specific other does not only depend on the characteristics of this specific other (that is, her or his contributions in the public good game) but also on the social value orientation of the subject. This is indeed what we find. Table 2 shows a linear regression with the post-test angle as dependent variable and the social value orientation of the subject and the contributions of the specific other as independent variables. Both variables appear to have a large impact.

Table 2 Linear regression with the angle measured by the post-test as a dependent variable and, as independent variables, the angle measured by the pre-test and the contributions of the other subject in periods 1-25.

	<i>B</i>	<i>SE B</i>	<i>Beta</i>	<i>t</i>	<i>Sign. t</i>
Social Value Orientation	.366	.086	.298	4.279	.0000
Contributions of the other in periods 1-25	.126	.025	.355	5.099	.0000
Constant	-15.118	4.536		-3.333	.0011

Multiple R: 0.465

Adjusted R Square: 0.207

A priori one cannot exclude the possibility that subjects develop a general attitude towards their group, reflecting how well the group did in the public good game, and base their decisions in the post-tests only upon this. Alternatively, subjects may actively discriminate between their group members and have a more positive attitude towards those group members who contributed more in the public good game. The correlation results reported above suggest that the latter motivation is at work. To test this more directly we will now look at intra-person comparisons. As discussed in section 2, we developed the circle-test specifically for this purpose. The idea is that if member A contributes more (less) than member B, the social tie with

A is more positive (negative) than with member B. As a test we compute across all subjects the correlation between, on the one hand, the difference in the post-test angles regarding alternative pairs of group members and, on the other hand, the difference in the contributions in period 1-25 of these group members. It turns out that the Pearson correlation is 0.57 (significant at the .001 level), which shows that during the public good game the subjects have built specific bonds with specific group members, rather than a general 'group cohesion'. We will come back to this in section 3.3.

Impact of social ties

An interesting question is whether the attitudes of the subjects towards each other influence their behavior in the public good game. First we test whether the social value orientation, as measured in the pre-test, affects behavior in the first periods of the public good game. This does not appear to be the case, since no correlation is found between the pre-test angles and the contributions in the first period or the first five periods. Many of the subjects with a pre-test angle of θ nevertheless contribute (substantially) more than the 'Nash equilibrium' strategy would imply in that case (3 per period). A possible explanation is that some selfish subjects anticipate the presence of conditional cooperators who only contribute if they believe sufficient others will (Keser and van Winden 2000; see also Sonnemans, Schram and Offerman 1999).

Positive sentiments in the post-test, meaning that the group members care for each other earnings, should decrease the commonly found end-effect of declining contributions. We calculate the correlation between a subject's contributions in the periods 26-32 with the average of the three angles of the post-tests of that subject. The mean post-angle per subject correlates highly (Pearson $R=0.59$, $p<0.001$) with the sum of the contributions in period 26 to 32. As is to be expected, the correlation with behavior (contributions) in the first 25 periods is much weaker (Pearson $R=0.29$).

3.3 Typology of social ties and the network of social ties within groups

So far, we have focused on one-sided sentiments (angle post test) and one-sided social ties (difference angle post and pre test), neglecting whether these are also mutual (see footnote 4). In this section mutual sentiments and ties are examined. Furthermore, we will look at the group structure, that is, the network of social ties within a group. More specifically, can we observe homogeneity within groups?

Table 3. Mutual sentiments and social ties.

		Sentiments towards specific subjects	Social ties
Type	Sign	Percentage of pairs	Percentage of pairs
symmetric	++ mutually positive	29	10
	-- mutually negative	0	5
	00 mutually neutral	22	19
asymmetric	+0 positive-neutral	37	22
	+- positive-negative	4	10
	0- neutral-negative	8	34
sum		100	100

Note: neutral attitudes (0) are defined by angles between -5° and $+5^\circ$.

The first question that arises is whether a tendency exists towards symmetric mutual sentiments and ties. Table 3 shows the results. Sentiments are neutral and ties are absent in approximately 20% of the cases. Mutually positive sentiments occur in approximately 29% of all pairs. As mutually negative sentiments are absent, symmetry of (non-neutral) sentiments also occurs in 29% of the cases. Social ties show a different outcome. Mutually positive ties occur only in 10% of the cases, and (non-neutral) symmetric ties in general occur in 15% of the cases. Asymmetry is much more common (66%). It is concluded that, in our public good environment, interaction among individuals with equal endowments and payoff structures does not lead to pervasive positive ties among them. Apparently, individual differences in social value orientation and reaction patterns that cannot be controlled for, result in complex dynamics. The suggestion borne out by the ‘minimal group paradigm’ literature and social identity theory (see Tajfel and Turner 1986, Taylor and Moghaddam 1994) that bonds form easily and lead to behavior favoring formal group members, needs to be qualified. Our results indicate that once interaction is allowed group cohesion can no longer be taken for granted.¹⁰

On the basis of our experimental results, social ties structures (social networks) are likely to differ widely among groups, depending on the success of the interaction. To examine this, we compare the two worst performing groups in terms of mean contributions to the public good with the two best performing groups. Table 4 presents a comparison of the different types of ties in these groups. Whereas most of the ties in the best performing groups are (mutually)

¹⁰ Note that if behavior in the circle test would be motivated by inequality aversion, we would typically observe positive-negative combinations of sentiments, with the rich participant (a free rider) giving to the poor one who

positive, most of the ties in the worst performing groups are either negative or neutral. Figure 6 shows the social ties structures in these groups. The networks of the two worst groups are quite similar, as are the networks of the successful groups. Among them the two types of networks differ considerably. Note, however, that also in the groups with successful interaction (groups 2 and 12), networks are far from complete and asymmetry of ties occurs.

contributed a lot (+) and the poor taking from the rich (-). This is observed in only 4% of the cases.

Table 4. Comparison of social ties in the two worst and the two best performing groups.

	two worst groups				two best groups

4. Conclusion

This experimental study of the development of social ties structures in groups shows two main results. First, in line with the findings of van Dijk et al. (2002) for dyads, we find that prolonged functional interaction in a public good game leads to the development of social ties, the valence of which depends on the success of the interaction in terms of contributions to the public good. Since a social tie refers to the difference between the weight that an individual attaches to the well-being of a specific other and the weight given to the well-being of a generalized (randomly selected) other, the success of the interaction is partly determined by the individual's social value orientation, which measures the latter weight. In this respect our results corroborate earlier findings indicating that subjects already start out with very different distributional preferences. These preferences appear to change due to affective responses to the beneficial or harmful behavior of those interacted with. In the experiment this happened with 54% of the subjects.

Second, subjects discriminate between group members on the basis of their relative contributions, that is, relative to the contributions of other group members. The resulting dynamics appears to generate a variety of social ties between group members. Most (66%) of the ties turn out to be asymmetric, notwithstanding the shared interest in the public good, the equal endowments and the identical payoff structures. This study suggests that individual differences in social value orientation and (affective) reaction patterns that are not controlled for are responsible for this. Focusing on the best and worst performing groups in terms of contributions to the public good, we find that the nature of the social ties structures (networks) differs considerably between groups. Whereas most of the ties among members of the best performing groups are (mutually) positive, most of the ties in the worst performing groups are either negative or neutral. However, also in the successful groups networks are far from complete and asymmetry occurs.

In the experiment payoff structure and endowments are identical for all individuals, yet very different outcomes are realized, depending on social value orientations and individual reaction patterns. In modern language, even under favorable circumstances social capital in the form of positive social ties cannot be taken for granted. For organizations, an implication is that not only the choice of incentive structure is relevant, but also the effort devoted to getting the most out of the selected incentive structure. Changing counterproductive group dynamics may require actively intervening in the group's composition or undertaking specific tasks to enhance understanding and positive affect between group members (team building). Although this

insight will not be new for managers who have to manage professional working teams, it is rarely acknowledged in the economics literature.

Appendix

SUMMARY OF THE INSTRUCTIONS

The instructions of all three parts of the experiment are fully computerized. To save space we provide only a summary of the three parts of the experiment.

Part 1

You are asked to make a single choice. The choice concerns the allocation of points to yourself and to a randomly chosen other subject ('the other'); 200 points equal 1 guilder. Your options are depicted on the next screen. Each point on the circle gives a combination of points you receive or lose and points the other receives or loses. Choose now a point on the circle with the mouse. When you click, the corresponding points for you and the other are revealed. By clicking on other points of the circle, other combinations you may choose become visible. You are now asked to answer two questions to check your understanding <...not reproduced here...>.

The other subject with whom you will be linked has to take a similar decision. Your reward is determined by your own choice and the choice of the other. During the experiment you will not receive any information about the choice made by the other. When you get paid out, once the whole experiment has finished, you will be informed about the choice of the other.

To check your understanding of the procedure, we will ask you two further questions <...not reproduced here...>. The exercises are finished. You are now asked to choose a combination of points for yourself and of points for the other.

Part 2

Introduction

Part 2 consists of 32 periods. In each period you are asked to take a decision. Each decision concerns the distribution of 10 markers over two activities: activity X and activity Y.

Activity X leads to a payoff for yourself only. Activity Y leads to a payoff for yourself and also for three other subjects. Each of the three other subjects has to take similar decisions: activity X leads to a payoff for her/himself only. Activity Y leads to a payoff not only for this participant, but also for you and the other two participants. After each period you are informed about the decisions of the three others. You will be paid after the end of the experiment.

To avoid any misunderstandings: the subject you were paired with in the first part of the experiment is not among the three subjects you will now be linked with. Part 1 and Part 2 are completely independent of each other.

The three subjects with whom you will interact are called A, B and C. During all 32 periods A, B and C remain the same subjects.

Payoff information

On the next screen the upper-left corner shows you a summary of how your payoffs from the activities X and Y are determined. This summary remains visible during the experiment.

Your payoff from activity X depends on the number of markers you yourself spend on this activity. The column 'value' shows the payoff of each marker that you spend on activity X. As you see, each extra marker pays you less. The column 'sum' shows you the total payoff for each number of markers that you spend on X.

Your payoff from activity Y depends on the total number of markers that you and the other three participants spend on this activity. Each marker pays you and each of the three others 7 points.

In each period fixed costs will be subtracted from your payoffs, namely 60 points. Thus, your total earnings per period will be: the payoff from activity X PLUS the payoff from activity Y MINUS the fixed costs.

On your handout 'Overview of earnings and costs per period' you find the same information as you can see now in the upper-left corner of your screen. On the other handout 'Table of total earnings' the earnings for all possible combinations of markers allocated to activity X and Y are listed.

Making a decision

We will now practice how decisions are taken. On the next screen you are instructed how to type in your decision. First you type in how many of your 10 markers you want to spend on activity X. Then, the number of markers for activity Y. You will subsequently be asked to confirm your decision. After confirmation you cannot change your decision anymore.

Registration table

At the bottom of the screen, you see now the REGISTRATION TABLE. In this table your decisions, the decisions of the three others and the earnings are recorded. This table will always be visible.

Questions and exercises

To check your understanding of the experiment you are now requested to answer some questions and to do a number of exercises. <.....>

You are ready now with the exercises. Period 1 will start, once all participants are ready.

Periods 1-25

After period 25

We interrupt part 2 of the experiment and start with the third part. After part 3 has finished, we will continue with part 2.

Part 3

You will be asked the same question as in part 1, namely to choose between several combinations of points for yourself and for another. However, this other is not randomly chosen as was the case in part 1, but is one of the participants with whom you are linked in part 2. You will be asked to take three decisions. In these three decisions the other is, subsequently, participant A, B and C of part 2 of the experiment. The others will take similar decisions. Your earnings are again determined by your own decisions and the decisions by the other three participants. Also during this part of the experiment you will not receive information about the decisions of the others. Only after the experiment you will be informed about your earnings.

To refresh your memory, we ask you to do an exercise. You are ready with the exercise. You are now asked to take the three decisions. <.....>

Part 3 of the experiment has finished. As soon as everybody is ready, we will continue with part 2.

Continuation of part 2: periods 26-32.

OVERVIEW OF EARNINGS AND COSTS PER PERIOD

EARNINGS MARKERS IN X

MARKER	VALUE OF MARKER	SUM
1	20	20
